## **Rolling Cylinders**

A thin-walled cylinder of mass M and rough inner surface of radius R can rotate about its fixed central horizontal axis OZ. The Z-axis is perpendicular to and out of the page. Another smaller uniform solid cylinder of mass m and radius r rolls without slipping (except for question 1.8) on the inner surface of M about its own central axis which is parallel to OZ.

- 1.1) The rotation of M is to be started from rest at the instant t=0 when m is resting at the lowest point. At a later time t the angular position of the centre of mass of m is  $\theta$  and by then M has turned through an angle  $\phi$  radians. How many radians (designated  $\psi$ ) would have mass m turned through about its central axis relative to a fixed line (for example, the negative Y-axis)? Give your answer in terms of  $\theta, \phi, R$  and r. (0.8 point)
- 1.2) What is the angular acceleration of m,  $\frac{d^2}{dt^2}\psi$ , about its own axis through its centre of mass? Give your answer in terms of R, r, and derivatives of  $\theta$  and  $\phi$ . (0.2 point)
- 1.3) Derive an equation for the angular acceleration of the centre of mass of m,  $\frac{d^2}{dt^2}\theta$ , in terms of m, g, R, r,  $\theta$ ,  $\frac{d^2}{dt^2}\phi$ , and the moment of inertia  $I_{\text{CM}}$  of m about its central axis. (1.8 points)

Page 2 of 2

- 1.4) What is the period of small amplitude oscillation of m when M is constrained to rotate at a constant angular velocity? Give your answer only in terms of R, r, and g. (1.3 point)
- 1.5) What is the value of  $\theta$  for the equilibrium position of m in question 1.4? (0.2 point)
- 1.6) What is the equilibrium position of m when M is rotating with a constant angular acceleration  $\alpha$ ? Give your answer in terms of R, g, and  $\alpha$ . (0.7 point)
- 1.7) Now M is allowed to rotate (oscillate) freely, without constraint, about its central axis OZ while m is executing a small-amplitude oscillation by pure rolling on the inner surface of M. Find the period of this oscillation. (2.5 points)
- 1.8) Consider the situation in which M is rotating steadily at an angular velocity  $\Omega$  and m is rotating (rolling) about its stationary centre of mass, at the equilibrium position found in question 1.5. M is then brought abruptly to a halt. What must be the lowest value of  $\Omega$  such that m will roll up and reach the highest point of the cylindrical surface of M? The coefficient of friction between m and M is assumed to be sufficiently high that m begins to roll without slipping soon after a short skidding right after M is stopped. (2.5 points)
